### ABSTRACT

Pinhole-free thin films deposited by glow discharge or plasma polymerization of organosilanes, organosilazones and organosiloxanes for use as reactive ion etch oxygen barriers in multilayer resist structures, of lift-off masks, for fabrication of semiconductor devices, such as integrated circuits. The process includes deposition of thin plasma polymerized organosilicon barrier film over a radiation insensitive polymeric base layer previously coated on a substrate, followed by thermal annealing of the plasma polymerized barrier layer, over which is then coated a radiation sensitive resist layer. After definition of the desired resist pattern by imagewise exposure and development, the image is etch transferred into the barrier layer by reactive sputter etching in a fluorine containing ambient, and subsequently transferred into the base layer, down to the substrate, in an oxygen plasma, during which time the plasma deposited film functions as an oxygen barrier. Final metal patterns are formed by metallization and lift-off steps.

## USE OF PLASMA POLYMERIZED ORGAOSILICON FILMS IN FABRICATION OF LIFT-OFF MASKS

This is a division of Ser. No. 452,549 filed Dec. 23, 1982, now U.S. Pat. No. 4,493,855.

### DESCRIPTION

#### 1. Technical Field

This invention relates to the fabrication of semiconductor components such as integrated circuits, and more particularly to the use of thin films deposited by glow discharge or plasma polymerization of organosilicon monomers as oxygen reactive ion etch barriers during pattern delineation in high resolution lithography processes for large scale integrated circuitry.

One object of this invention is to provide a method for forming defect-free polyorganosilicon films.

Another object of this invention is to provide pinhole-free oxygen RIE barrier for lift-off masks employed in the fabrication of semiconductor components.

Another object of this invention is to provide novel and improved oxygen RIE barrier films for lift-off masks employed for forming interconnecting metal-lurgy systems for semiconductor components.

Another object of this invention is to provide a lift-off mask with improved oxygen barrier layers which eliminate interlevel shorts caused by pinholing occasioned in conventional oxygen RIE barrier films, such as silicon oxide and silicon nitride.

Another object of this invention is to provide a pinhole free plasma polymerized oxygen barrier film formed from non-pyrophoric organosilicon monomers which are liquids at room temperature as an improved replacement for silicon oxide and nitride barrier films which are normally formed from hazardous silane ( $\text{SiH}_4$ ) and disilane ( $\text{Si}_2\text{H}_6$ ) gases. The films thus prepared are useful as oxygen etch barrier with good dielectric properties.

#### 2. Background Art

With continued miniaturization of semiconductor integrated circuits to achieve greater component density and smaller units, as in large scale integrated circuits, it is required that high resolution lithographic processes be developed for dense metallization networks. A major factor limiting resolution of micron and submicron resist images in electron beam lithography using single layer thick resist films, is the proximity effect due to electron scattering. As a result, multilayer resist approaches that employ thin imaging layers to eliminate or minimize the problems of proximity effect and having increased resist sensitivity are receiving an increased focus of attention by the research and development areas for submicron lithography. Similarly, in optical lithography using refractive projection mask aligners, multilayer resist processes overcome the problems of resolution and aspect ratio because of depth of field limitations in the case of single layer resist images.

A trilayer resist process for integrated circuit devices, typically, comprises a radiation insensitive polymer base layer, a thin  $\text{O}_2$ /RIE resistant barrier layer and a thin E-beam, UV or X-ray resist layer. The polymeric base layer is generally applied by spin-coating on a substrate followed by a curing step and deposition of the  $\text{O}_2$ /RIE barrier film which is overcoated with a thin coating of an imaging (resist) layer. The  $\text{O}_2$ /RIE barrier films conventionally employed in the prior art are

mostly inorganic in nature, such as plasma deposited silicon oxide, vacuum evaporated  $\text{SiO}_2$ , sputtered quartz and chemical vapor deposited (CVD) silicon nitride. Further information can be obtained on reference to the Havas et al. U.S. Pat. No. 4,202,914; J. Moran, Pol. Eng. Sci. 20, 1097 (1980); L. Rothman, IBM Technical Disclosure Bulletin 23, 2293 (1980); and P. Grabbe et al. J. Vac. Sci. & Tech. 21, 33 (1982).

One method of employing these multilevel resist (MLR) techniques for forming metallization patterns on devices is commonly denoted by the term "expendable mask method", "lift-off method" or "stencil method", which was initially described in U.S. Pat. No. 2,559,389. Improvements to the basic "lift-off method" have been made, as for example, in U.S. Pat. Nos. 3,849,136; 3,873,361; 4,004,044 and 4,202,914.

In conformance with the foregoing, this "lift-off" method includes the use of organic polymeric material as a base or sub-layer on an integrated circuit substrate and an overlying oxygen RIE resistant layer of a diverse material, such as a metal layer, silicon dioxide, silicon nitride or a polydimethylsiloxane, having openings in a selected pattern. Where polydimethylsiloxanes have been proposed as oxygen RIE barrier films, they have been solution coated or cast on the polymeric base layer. See the above noted patent of Franco et al. U.S. Pat. No. 4,004,044, and L. Fried in IBM J. of Res. and Dev. 26, 362 (1982).

After deposition of the oxygen barrier mask, corresponding openings are conventionally formed or transferred in the polymeric base layer by reactive ion etching (RIE) in an oxygen ambient utilizing the overlying barrier film as a dry etch mask. The desired thin film, e.g. metal, to be deposited, is then blanket coated over the structure and on the surface exposed by the openings in the polymeric base layer.

When the polymeric base layer is removed by application of a solvent selective for it, the overlying barrier layer and thin film, above the barrier layer, "lift-off" to leave the thin film deposited in the selected pattern on the substrate.

Although, the conventional inorganic and solution coated polydimethylsiloxane films have been effective masking layers in  $\text{O}_2$ /RIE processes and have been employed in multilevel metal process for fabrication of integrated circuit devices, there are some problems encountered with these materials which detract from their consistency of function and thus renders that application less attractive in lithographic processes designed for submicron patterning. For example, coherent thin films of silicon oxide or silicon nitride are formed at relatively high deposition temperatures, e.g.  $200^\circ$ - $275^\circ$  C., which results in debris generation at the organic-inorganic interface, and thus problems of reticulation and shriveling are often encountered. A single major disadvantage of inorganic oxygen etch barrier films is a too frequent occurrence of high defect densities that are above the acceptable limits for high resolution lithographic applications. The solution coated or cast thin films of poly(dimethylsiloxanes) and "glass resins", on the other hand, have the problems of non-uniformity, thickness control and shelf life of polymer solutions due to the presence of a certain amount of reactive groups on the polymer chain.

### BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings forming a material part of this disclosure:

FIGS. 1A to 1H are diagrammatic cross-sectional views illustrating a portion of a substrate on various stages of processing during the practice of this invention: and

FIGS. 2A and 2B are photomicrographs illustrating transfers of images into a polysulfone layer from a pattern formed in an overcoating of a plasma polymerized organosilicon film.

## DISCLOSURE OF THE INVENTION

For further comprehension of the invention, one of the objects and advantages thereof, reference will be had to the following description and accompanying drawings, and to the appended claims in which the various features of the invention are more particularly set forth.

Briefly, the improved multilayer resists or lift-off process of this invention employs glow discharge or plasma polymerized organosilicon oxygen etch resistant films as improved replacement or substitutes for conventional inorganic silicon oxide or silicon nitride film in multilevel or lift-off processes for fine line lithography. The materials of this invention also provide novel and improved oxygen RIE barrier film over solution deposited films of polyorganosiloxanes such as "glass resins" or poly(dimethylsiloxane) resin.

Thin films deposited by glow discharge or plasma polymerization of organosilicon monomers are known to be useful as protective coatings for passivation and encapsulation, antireflection coatings for conventional optics, dielectrics in microelectronics, thin light wave guides, and moisture resistant barriers of alkali halide optics. Discussion and description can be found in U.S. Pat. Nos. 3,847,652; 4,013,532; 4,018,945; 4,137,365; 4,212,719; 4,226,896; 4,260,647; and 4,279,723; as well as the publications of M. Maisonneune et al., *Thin Solid Films* 33, 35 (1975); Y. Segui et al. *ibid* 50, 321 (1978); M. Aktik et al. *J. Appl. Physics* 51, 5055 (1980); M. P. Schrieber et al. *Thin Solid Films* 72, 487 (1980); and T. Hirotsu *J. Applied Poly. Sci.* 24, 1957 (1979).

The organosilicon polymers can be formed by glow discharge or plasma polymerization of monomers, of organosilicons including organosilanes, organosilazanes, organosiloxanes and mixtures thereof having the general configurations:

where

X=zero or oxygen, NH, NR<sub>2</sub>, CH<sub>2</sub> or

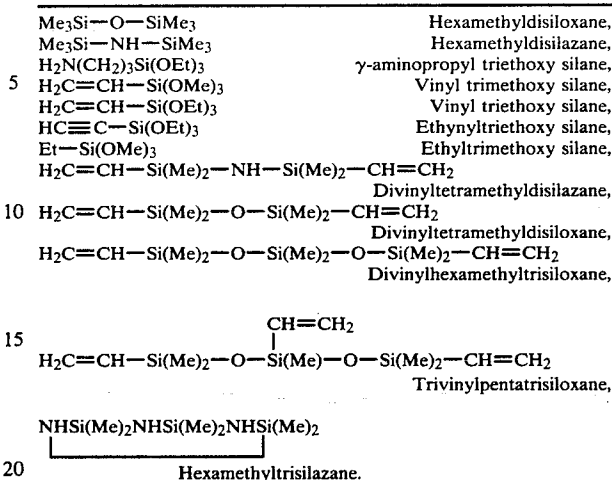

Y=OR<sub>1</sub> or R<sub>3</sub> group;

Z =  $-\text{CH}=\text{CH}_2$ ,  $-\text{C}\equiv\text{CH}$ ,  $-\text{OR}_1$ ; phenyl or an aminoalkene group;

R is  $\text{CH}_3$ ,  $-\text{CH}=\text{CH}_2$ , OR,  $-\text{O}-\text{Si}-\text{R}$ , or  $-\text{O}-\text{Si}-\text{CH}=\text{CH}_2$ ; and

R<sub>1</sub> R<sub>2</sub> and R<sub>3</sub> are alkyl groups, preferably having from 1 to 3 carbon atoms.

Illustrative of the material contemplated are:

These materials can be used singly or in admixture with each other. The composition can be readily varied to in accordance with desired film properties in terms of hydrophobicity and thermal stability, mechanical strength, adhesion, compatibility with contacting surfaces and oxygen etch rates. The plasma polymerized organosilicon films obtained are thermally stable when heated up to 450° C., they are resistant to most development and lift-off solvents, have good adhesion to contacting organic layers and have essentially zero etch rate in O<sub>2</sub> plasma or RIE, but can be etched by RIE in ambients containing CF<sub>4</sub>, CHF<sub>3</sub>, or CF<sub>4</sub>/O<sub>2</sub>. These films can also be employed as interlayer between organic or organic-inorganic polymer films without requiring application of adhesion promoters or other surface modifications.

The MLR or "lift-off" mask is completed by overcoating the plasma polymerized organosilicon barrier layer, with a blanket layer of a photo, UV, X-ray or electron beam (E-beam) resist, which is patterned, using standard photo, UV, X-ray or E-beam lithographic techniques, to form a pattern of openings corresponding to a desired conductor pattern which concurrently exposes a corresponding pattern of the plasma polymerized barrier layer. Using the patterned resist as a masking layer, conformal openings can be suitably formed in the barrier layer by reactive ion etching in a suitable ambient which, as indicated above, can comprise a  $\text{CF}_4$  ambient.

This is normally followed by suitable etching of conformal opening in the lift-off mask base layer, again, by reactive ion etching, normally, in the same sputtering chamber in which, for a polysulfone base, the ambient can be switched, with purging, to an oxygen containing ambient to which the plasma polymerized organosilicon is essentially resistant. As will be appreciated, the formation of the indicated conformal openings in the lift-off base layer exposes a corresponding pattern of the substrate. It is noted, that the resist layer is removed coincidentally by  $O_2$ /RIE etching of the lift-off base layer (e.g. polysulfone).

After removal of the resist layer (which may be con-  
currently with  $O_2$ /RIE etching of the base layer), a  
blanket layer or coating of a conductive metal, for ex-  
ample, aluminum based alloys such as a 96/4 alumi-  
num/copper alloy, is deposited (e.g. by sputtering or

vacuum deposition) over the MLR on lift-off mask exposed plasma polymerized barrier layer as well as over the exposed portions of the substrate. This is followed by exposing the substrate to a solvent that is selective to the lift-off base layer (e.g. polysulfone). On solvation of the base layer component, all superimposed films and layers will lift-off to expose the remaining portions of the substrate complementary to the retained metallization pattern.

This invention also comprehends the deposition of modified plasma polymerized polyorganosilicon by the inclusion of organoborons (as for example trimethyl boroxine,  $B(OMe)OB(OMe)OB(OMe)O$ ) in the plasma polymerizing ambient. The resultant plasma polymerized organometallic polymer film can then be treated in an oxygen plasma (as for example a conventional oxygen plasma resist asher), which will convert the surface of the film as well as a surface adjacent portion thereof into a mixture of metal oxides which also function as an oxygen RIE barrier. The composite or modified film remains amenable to  $CF_4$  and  $CHF_3$  RIE etching.

Also, this modification not only permits the deposition of plasma polymerized organometallic polymer film, but also a further modification into completely or partially oxidized ( $O_2$  plasma) materials, as desired. The C and H content of the film can be decreased simply by injecting oxygen into the plasma system during deposition and increasing the pressure as required.

It may be noted that deposition of silicon oxide over moisture sensitive organic substrates or surfaces is known to suffer occasionally from the problem of reticulations, particularly when humidity levels are high. In the present modification, no such problems are encountered. The organosilicon polymers are deposited by plasma polymerization at ambient or at elevated temperatures while in the silicon oxide or nitride films are in general deposited at  $270^\circ$  to  $300^\circ$  C. Also, the present modification of the invention allows tailoring of expansion coefficients at the interfaces through varying of organic content of the plasma polymerized film by selection of an appropriate monomer.

#### Best Mode for Carrying Out the Invention

Referring to the drawings, and to FIGS. 1A to 1H in particular, there is shown a substrate 1 which is typically monocrystalline silicon or other semiconductor material (as for example, germanium, III-V compounds and the like), with an overlying layer 2 of a dielectric coating, as for example, silicon oxide,  $Si_3N_4$ , or composites thereof, and the like. It may be noted that plasma polymerized organosilicon films described in this invention are also useful as dielectric coatings on conductor and semiconductor materials. The substrate 1, in this embodiment of the invention is comprehended as an integrated circuit having active and passive devices fabricated therein (not shown, but illustrated by a diffused region 3) and means for electrically isolating the devices from each other. In such application, the insulating layer 2 is normally provided with contact openings (illustrated by 4) for making contact to active and passive devices. However, the substrate can also be a body of insulating material when this invention is employed to form metallurgical patterns on a dielectric module or carrier (e.g. alumina ceramics, glass-ceramics, etc.) for supporting integrated circuit chips or devices, and appropriate associated circuitry.

Next, as shown in FIG. 1A, a blanket layer 6 of a solvent soluble organic polymer, illustratively in the

range of 1 to 15 microns and preferably 1 to 3 microns, is deposited over substrate 1. Various suitable solvent soluble polymers can be used, as for example the polysulfone polymerized resin, many of which are described in U.S. Pat. No. 4,045,318. A typical polysulfone is sold under the trademark "ASTREL 360" by the 3M Company.

Another effective polymer which can be used for the base layer 6 is a conventional photoresist such as the AZ-1350 distributed by the Shipley Corporation, and which comprises a novolac-type phenol-formaldehyde resin and a o-quinonediazide photosensitive cross-linking agent. When this photoresist material (e.g. AZ-1350) is baked at about  $210^\circ$  C. to improve adhesion, to the substrate, the photoresist is rendered thermally stable as well as desensitized. The resist can be applied by any well known technique such as spinning, brushing, dipping and the like.

For purpose of illustration the polymeric base coating 6 can comprise of a polysulfone layer comprised of ICI polysulphone which was applied on silicon wafers by spin coating a 20 wt. % solution in diglyme N-methyl pyrrolidone solvent mixture and baked to form a coating thickness of 2  $\mu m$ .

Next, a blanket barrier layer 7 of the above-described plasma polymerized organosilicon films is deposited over the solvent soluble thermally cured base layer 6. As indicated above the barrier film 7 is resistant to reactive ion etching in an oxygen containing ambient, and can be applied in a thickness range of about 500 to about 3000 Å, and preferably from about 800 to 1500 Å. For the specific embodiment, a 1,000 Å thick barrier film 7 was deposited by plasma polymerization of divinyl tetramethyldisiloxane or hexamethyldisilazane which will serve as a barrier to oxygen RIE through in-situ oxidation to  $SiO_x$  like material. Thus, when this plasma polymerized film 7 was coated on a 2  $\mu m$  thick layer of polysulfone and the composite subjected to  $O_2$ /RIE, no measurable thickness loss was observed. Also, a plasma polymerized organosilicon film 7 was formed from 1,3-divinyl tetramethyldisiloxane or hexamethyldisilazane to a thickness of 1,500 Å on the above noted ICI polysulfone base layer 6, followed immediately by an annealing schedule of  $85^\circ$  C. for 5 minutes,  $200^\circ$  C. for 10 minutes and  $300^\circ$  C. for 10 minutes. Alternatively, the deposition was carried out directly on a substrate heated to  $100^\circ$ - $250^\circ$  C.

Plasma polymerization of organosilicon monomers was carried out by radiofrequency discharge using an inductively coupled RF generator operated at 13.54 MHz. The substrates were positioned downstream from the glow in a chamber equipped with a rotating stage and a Sloan quartz thickness monitor. Prior to introduction of the monomer vapor at a pressure of  $40$ - $50 \times 10^{-3}$  torr through the inlet tube, the deposition chamber is evacuated up to  $5 \times 10^{-3}$  torr. Under these conditions, with a power input of 5-20 watts, a deposition rate of 40-60 Å/minute was achieved, as measured by the quartz crystal. The plasma coatings obtained at ambient temperatures were subsequently annealed up to  $300^\circ$  C. on a hot plate or static oven. Various substrates employed were silicon, oxidized silicon ( $Si/SiO_2$ ) wafers, cured polyimide films coated on silicon substrates, polysulfones and baked AZ-type coatings. Plasma films deposited on silicon were analyzed by IR transmission spectra on Nicolet FTIR instrument and ESCA, before and after annealing. These IR spectra are characteristic of organosilicon polymers except for broadening of

various bands indicating complexity of polymer structure. The annealing step was found to cause increase in the Si—O—Si band intensity and decrease in the Si—C bands.

Measurements of pinhole density using Navonic Electrolysis Defect Detector, showed that the post-deposition annealing conditioned the plasma polymerized film to be consistently defect free, even after subjecting them to oxygen plasma or reactive ion etching in an oxygen ambient. Under the same conditions, 1,000 Å to 1,500 Å thick films of  $\text{SiO}_x$  showed 10–12 defects/cm<sup>2</sup>, while 1,200 Å thick films of silicon nitride showed 6 defects/cm<sup>2</sup>.

Also, as shown in FIG. 1C, a layer 8 of a photo, X-ray or E-beam resist, as for example on E-beam sensitive positive novolac/o-quinondiazide resist, of about 0.5 μm to 0.8 μm thickness is blanket coated over the barrier layer 6, by spin-coating. Openings 9A and 9B are then formed in resist layer 8 by conventional lithographic techniques well known in the integrated circuit fabrication art.

The exposed and patterned resist layer 8 is then used as a mask for reactive ion etching of the plasma polymerized barrier layer 7 to replicate in it the opening pattern of resist layer 8. Thus, openings 9A and 9B of resist layer 8 are effectively transferred into the plasma polymerized barrier layer 7 as respective openings 10A and 10B.

In reactive ion etching, the structure of FIG. 1D is placed in diode type system having an ambient of at least  $\text{CHF}_3$  at 25 sccm flow/25μ pressure/200 watts power density. An illustrative R.F. tool which can also be employed in etching the plasma polymerized barrier layer 7 is described in U.S. Pat. No. 3,598,710.

At this point, if desired the resist layer 8 can be removed by a suitable solvent selective for the resist but not for the base polymeric layer 6. However, as indicated above, the resist layer 8 can conveniently and preferably be removed concurrently with reactive ion etching of the polymeric base layer 6 in an oxygen ambient.

Thus, utilizing the composite barrier and resist layers 7/8, with the openings therein, as a mask, the polymeric base layer 6, is then apertured by reactive ion etching in an oxygen containing ambient. For a polysulfone base layer 6, the etching can be accomplished over 5–8 minutes at a pressure of 20–30μ at a power density of 200 watts/cm<sup>2</sup>, whereas for a desensitized Shipley AZ-1350 (a novolac/o-quinondiazide resist) base layer 6, the etching can be effective at about 100 millitorrs of  $\text{O}_2$  at a power density of about 0.25 watts/cm<sup>2</sup>. Alternately, the ambient could consist of  $\text{O}_2$  in combination with an inert gas such as argon, nitrogen and the like. In this manner, the openings 10A and 10B in barrier layer 7 are effectively transferred into the polymeric base layer 6 as respective openings 11A and 11B. As indicated above, the remaining portions of resist layer 8 are coincidentally removed by  $\text{O}_2$ /RIE etching of the polysulfone base layer 6.

It is noted that the successive reactive ion etching steps of FIGS. 1E and 1F can be conveniently accomplished in the same reactive ion etching chamber by first utilizing a fluorine containing gas ambient, for the barrier layer 7, followed by purging and substitution of an oxygen containing ambient for the polymeric base layer 6. As shown in FIG. 1F, the  $\text{O}_2$ /RIE etching of the polymeric base layer 6 can be continued to extend the etching (overetch) of the base layer 6 under the barrier

layer 7 to form the overhangs shown in FIG. 1F. These overhangs function to insure complete removal of the base layer 6 in openings 11A and 11B, provide for control of pattern dimensioning and insure of tearing of any overlaid coatings during lift-off of the mask, as more fully discussed in the above noted U.S. Pat. No. 4,004,044.

Next, using the lift-off composite 6A/7A of FIG. 1F with openings 10A/11A and 10B/11B, as a mask, a functional metal film 15 is blanket coated over the structure as shown in FIG. 1G. This metallic film 15 may be any metal conventionally used for metallization of devices in the semiconductor technology, e.g., aluminum, aluminum-copper alloys, platinum, palladium, chromium, etc. The metallization can be blanket coated by evaporation or sputtering over the surface of the structure (e.g. on the barrier layer 7A) on the portions of the substrate exposed by the openings 10A/11A and 10B/11B in the composite lift-off mask 7A/6A.

In the next operation, as shown in FIG. 1H, the lift-off mask (7A/6A) and all overlying layers of metallization 15, are then removed by exposing the substrate to a solvent specific to the polymeric base layer 6A of the lift-off mask. In the case of polysulfone base layer 6A, the solvent can be *n*-methylpyrrolidone at 60° C. enhanced by ultrasonic agitation. As shown in FIG. 1H, the resultant structure is provided with a metallization pattern comprised of deposited segments 15A and 15B.

In studies of plasma polymerized organosiloxane film, the following results were obtained. Thin plasma polymerized films from divinyltetramethyldisiloxane (DVS) hexamethyl disilazane (HMDS), hexamethyldisiloxane (HMS), vinyltrimethoxysilane (VTS), and  $\gamma$ -aminotriethoxypropyl silane (A-1100) were deposited on silicon wafers placed downstream from the glow in an inductively coupled RF plasma system at 13.56 MHz, and tested for defects, thermal stability and solvent resistance.

Defect density evaluation was by the bubble trail method using Navonic Electrolysis Defect Detector. These plasma films were deposited at 700 Å, 1,200 Å, 1,500 Å and 2,000 Å thickness on silicon wafer which were then annealed at 300° C. and examined for defects at 10<sup>6</sup> V/cm in methanol. On 2.8 cm<sup>2</sup> areas screened for each thickness, no pinholes were observed as indicated by the absence of bubble trails. On treatment in oxygen plasma or RIE the films were found to be consistently defect-free. Upon  $\text{O}_2$  ashing (plasma treatment) for 5–10 minutes at 200 watts/0.8 torr  $\text{O}_2$  pressure in a Tegal Plasma System, these films remained mostly defect-free with one defect/cm<sup>2</sup> detected in some cases. When tested under the same conditions, a 1,660 Å  $\text{SiO}_2$  film, on silicon wafers, showed 10–15 defects per cm<sup>2</sup>.

Plasma polymerization of DVS was also carried out in the presence of argon at 80:20 DVS to argon ratio. A 1,500 Å thickness of deposited film showed no detectable pinholes when tested as above.

When tested for thermal stability, the plasma polymerized DVS, HMDS, HMS and VTS films are found to be stable up to 400° C.

Thermally annealed plasma polymerized films were found to be insoluble in common organic solvents, including NMP (*n*-methyl pyrrolidone).

With respect to contact angles, the as-deposited plasma polymerized films on silicon substrates, have  $\theta_{\text{H}_2\text{O}}$  80°–82° C. indicating a hydrophobic surface. When annealed up to 300° C. under nitrogen, the decreased contact angle of  $\theta_{\text{H}_2\text{O}}$  (76°–78° C.) was ob-

tained. The contact angle is reduced to  $\theta_{H_2O}$   $10^\circ$ – $15^\circ$  when the film surface is modified by a brief oxygen plasma ashing (treatment) in the above noted Tegal plasma ashing system.

FTIR analysis of the plasma polymerized films is typified by DVS deposited on KBr discs, showed characteristic vibration frequencies for C—H ( $2955\text{ cm}^{-1}$ ), Si—O ( $1032\text{ cm}^{-1}$ ), Si—C ( $839\text{ cm}^{-1}$ ) and Si—(CH<sub>3</sub>)<sub>3</sub> ( $839\text{ cm}^{-1}$ ). ESCA data for some of the plasma polymerized organosilicon films is given in Table I.

The spectral measurements were made with films deposited on gold coated substrates.

TABLE I

PLASMA DEPOSITED ORGANOSILICON FILMS: ESCA DATA*								
	DVS		HMDS		A-1100		VTS	
	A	B	A	B	A	B	A	B
O/C	.18	.55	.09	.17	.42	.65	.77	.99
Si/C	.31	.49	.36	.41	.20	.31	.32	.45
Si/O	1.76	.93	4.0	2.4	.47	.47	.42	.45
N/C	—	—	.19	.16	.10	.10	—	—
N/O	—	—	2.0	.94	.24	.15	—	—
N/Si	—	—	.5	.40	.51	.32	—	—

A = Data for the as-deposited films, 1500–1700 Å

B = Data for the films after annealing up to 300° C. in static oven

\* = Values are corrected for respective sensitivities and are the average of triplicate analysis for DVS and duplicate for all others.

DVS = Divinyltetramethyldisiloxane

HMDS = Hexamethyldisilazane

A-1100 =  $\gamma$ -aminopropyltriethoxysilane

VTS = Vinyltrimethoxysilane

A 1,500 Å thick plasma polymerized DVS film (annealed up to 300° C. followed by a 30 second oxygen ashing in the Tegal Plasma System) was employed as an oxygen barrier in a tri-level resist structure composed of 1.1  $\mu\text{m}$  thick polysulfone as the base layer and 0.85  $\mu\text{m}$  thick phenol-formaldehyde/o-quinone diazide positive imaging (resist) layer. E-beam exposure at 10  $\mu\text{m}$  C/cm<sup>2</sup> and conventional development gave clearly resolved 1  $\mu\text{m}$  and 1.5  $\mu\text{m}$  geometries. Reactive ion etching with CHF<sub>3</sub> followed by O<sub>2</sub> allowed image transfer through the barrier into the polysulfone base layer, as shown in FIGS. 2A and 2B.

In a modification of this invention, as discussed above, a 1,000 Å thick barrier film 7 was deposited on a 1.8  $\mu\text{m}$  thick layer 8 of polysulfone by plasma polymerization of a 1:1 mixture of divinyltetramethyldisiloxane and trimethoxyboroxine to provide an effective oxygen/RIE barrier for the etching of the polysulfone. When a 8,000 Å film of a novolac/o-quinonediazide

resist was used on top as an imaging layer 8 at 10  $\mu\text{m}$  C/cm<sup>2</sup> E-beam dose, after usual development, the image could be transferred cleanly to the barrier layer 7 by CHF<sub>3</sub>—RIE, and 1  $\mu\text{m}$  and submicron lines could be opened. The image was then etched (O<sub>2</sub>—RIE) through the polysulfone base layer 6. Here, the organometallic plasma polymerized film 7, upon exposure to O<sub>2</sub>—RIE (e.g. etching of base layer 6) is converted in-situ, at top surface adjacent portions, to SiO<sub>x</sub>BO<sub>y</sub> mixtures, which serve as an oxygen etch mask.

Also, the incorporation of boron into the plasma polymerized organosilicon polymers, enhances its CHF<sub>3</sub>—RIE rate. The CHF<sub>3</sub> etch rate for plasma polymerized layers of divinyltetramethyldisiloxane is 50 Å/min, while a plasma polymerized film from a monomer mixture of trimethoxyboroxine with divinyltetramethyldisiloxane gave a film with an etch rate of 140 Å/min under the same conditions.

While the invention has been particularly shown and described with reference to the preferred embodiments thereof, it will be understood by those skilled in the art that various changes in form and detail may be made therein without departing from the spirit and scope of the invention.

What is claimed is:

1. A method of depositing a layer on a monocrystalline silicon substrate comprising:

A. forming on a portion of said substrate a film by plasma polymerizing said film from an ambient containing monomers selected from the group consisting of organosilicons, including organosilanes, organosilazanes, organosiloxanes, and mixtures thereof;

B. heat treating said film at a temperature between about 85° C. and about 400° C.; and

C. treating said film in an oxygen plasma.

2. The method of claim 1 wherein said plasma polymerizing ambient includes organoboron monomers whereby said formed film comprises an organoborosilicone polymer barrier film, and said oxygen plasma treatment forms a borosilicate surface layer on said barrier film.

3. The method of claim 2 wherein said organoboron monomers comprise trimethoxy boroxine.

4. The method of claim 1 wherein said substrate is heated to between about 100° to about 300° C.
